Received February 8, 1973

Observation of the visible fluorescence of the SiF radical in SiF<sub>4</sub> gas irradiated by the pulsed output of a CO<sub>2</sub> laser leads to the conclusion that the molecules are dissociated into electronically excited fragments by the action of the intense laser field. A clear distinction is observed between the fluorescence produced through this process and that associated with thermalization of the incident energy.

L'observation de la fluorescence visible du radical SiF dans le gaz SiF<sub>4</sub> irradié par le faisceau pulsé d'un laser au CO<sub>2</sub> conduit à la conclusion que les molécules sont dissociées en fragments électroniquement excités par l'action du champ laser intense. Une nette distinction est observée entre la fluorescence produite selon ce procédé et celle qui est associée avec la thermalisation de l'énergie absorbée.

## RAMAN INTENSITY AND MODE-ENERGY

---

Raman transition probabilities are proportional to quantum number  $n$

$$W_{n \rightarrow n+1} \sim n + 1, \quad W_{n \rightarrow n-1} \sim n$$

So Raman intensities are proportional to the energy in the mode

$$I_{AS} \sim \sum_{n=0}^{\infty} W_{n \rightarrow n-1} N(n) \sim \sum_{n=0}^{\infty} n N(n) \sim \sum_{n=0}^{\infty} n N(n) = E_R / h\nu_R$$

$$I_S \sim \sum_{n=0}^{\infty} W_{n \rightarrow n+1} N(n) \sim \sum_{n=0}^{\infty} (n + 1) N(n) \sim 1 + \sum_{n=0}^{\infty} n N(n) = 1 + E_R / h\nu_R$$

The anti-Stokes signal divided by the room temperature Stokes signal is a direct measure of the mode energy

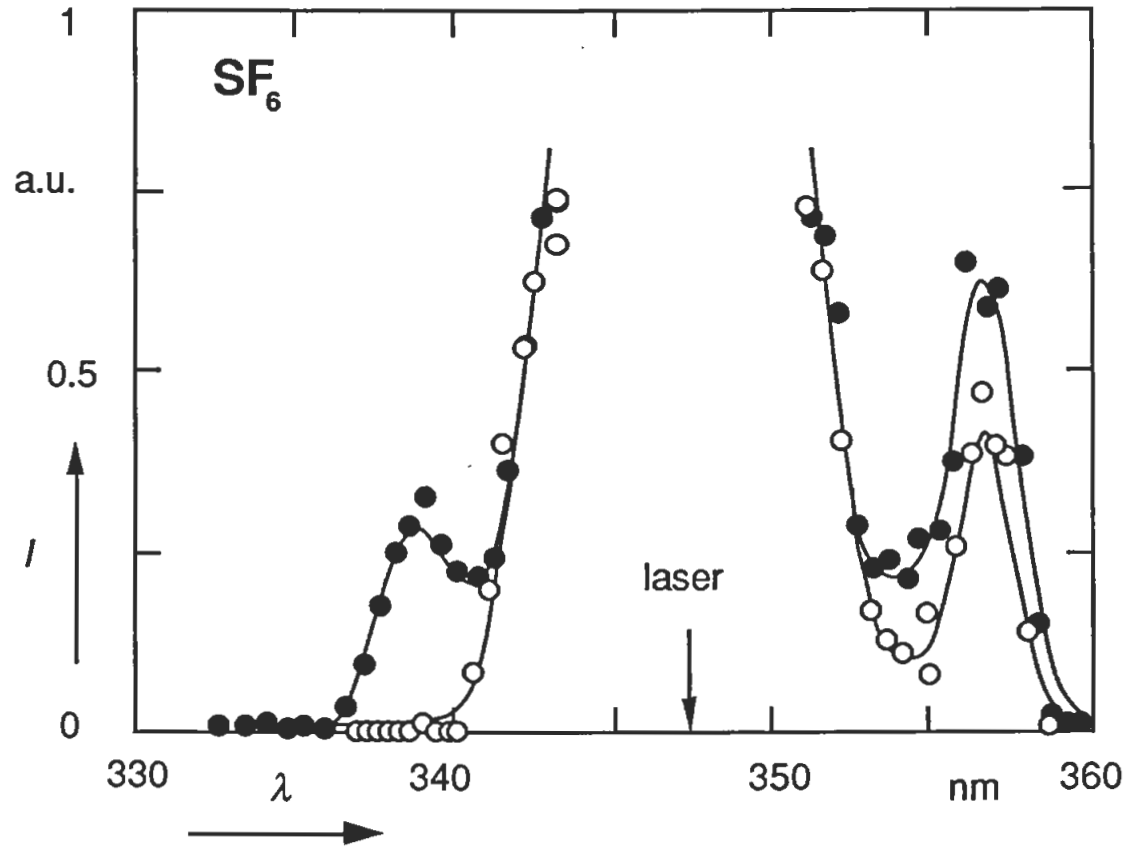

$$I_{\text{norm}} = \frac{E_R / h\nu_R}{1 + E_R^0 / h\nu_R} \approx \frac{E_R}{h\nu_R}$$

## OVERVIEW OF RESULTS

---

### Spontaneous Raman:

$\text{SF}_6$       Equilibrium vibrational energy distribution is reached within 20 ns

$\text{CF}_2\text{Cl}_2$       Nonequilibrium vibrational energy distribution for two modes

Total vibrational energy at least  $21,000 \text{ cm}^{-1}$

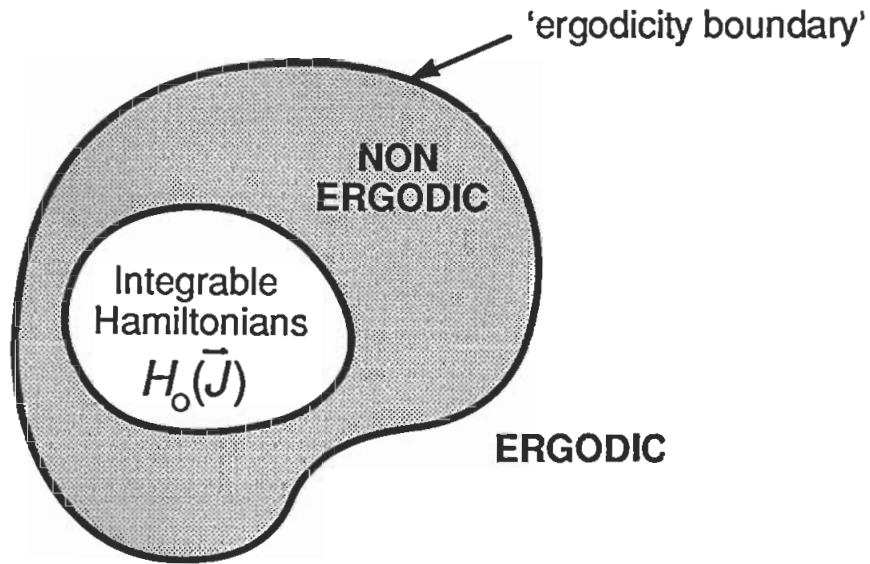

Pump mode contains most energy

Buffer gas equilibrates the energy distribution

### CARS:

Complete ground state depletion

# INTEGRABLE HAMILTONIANS

# NONINTEGRABLE PERTURBATIONS

Fermi, Pasta & Ulam (1955)

$$\sum_{\{n\}} n_i v_i = 0$$

**KAM THEOREM:** If  $v$ 's linearly independent and perturbation small  $\rightarrow$  trajectory surfaces are not destroyed, just distorted.

## NOTES

In the rest of this presentation, we will look at IRMPE from a classical nonlinear dynamics point of view.

In classical mechanics, a polyatomic molecule can be modeled as a system of coupled nonlinear oscillators.

Then, IRMPE can be thought of as a system of coupled nonlinear oscillators driven by an external oscillatory force.

From experiments we know that at low excitation, the energy is localized in the pump mode, while at high excitation the energy can be transferred to other modes.

The question of interest here is how the state of the molecule evolves from one with localized vibrational energy to one with distributed energy. Also, one would like to know what determines the final energy distribution.

For an integrable system, the trajectory is limited in a small part of the available phase space because of the constants of motion. And the energy is always localized. For example:

## NOTES

While for nonintegrable systems the trajectory can be very irregular.

For sufficiently high excitation or strong intermode coupling, the trajectory may cover the entire available phase space.

In this case, the energy distribution is equilibrium.

## NOTES

### NONINTEGRABLE PERTURBATIONS

**Q.:** Will a small nonintegrable perturbation render the system ergodic?

**Fermi, Pasta & Ulam:** Small nonintegrable perturbations *do not* make an integrable system to ergodic

**KAM theorem:** Small nonintegrable perturbations can only distort, not destroy the trajectory surfaces, *unless* the following condition is satisfied:

$$\sum_{(n)} n_i v_i = 0$$

140-55-18

Since nonintegrable perturbations such as mode-couplings can render the trajectory chaotic and energy distribution equilibrium, it was thought that these perturbations is responsible for the ergodicity of the system.

Intended to show that the general assumption of ergodicity in Boltzmann's statistical mechanics is a nature consequence of the inevitable small nonintegrable perturbations, Fermi, Pasta & Ulam studied the following question:

Both Fermi's experiment and the KAM theorem suggest that, in general, a system of nonlinear oscillators can become ergodic only when the energy involved is large enough, or when condition \*\* is satisfied.

## NOTES

It is interesting to compare the number of times condition \*\* is satisfied for the two molecules, SF<sub>6</sub> and CF<sub>2</sub>Cl<sub>2</sub>, whose energy distribution have been measured experimentally.

According to the KAM theorem, the more often condition \*\* is satisfied, the more likely the molecule will behave ergodically after infrared multiphoton excitation. For SF<sub>6</sub> and CF<sub>2</sub>Cl<sub>2</sub>, one can calculate the number of times condition \*\* is satisfied as a function of the excitation energy, and compare the results of the calculation with the experimental results.

of the equation is chosen close to the total anharmonicity of a typical vibrational mode, which can be roughly thought of as the linewidth of a typical  $\nu_i$ . Since our goal is to compare the number of incidences where Eq. (1.1) is satisfied for different molecules under the same conditions, the choice of the number on the right hand side of Eq. (1.2) is not critical. In the calculation the set  $\{n_i\}$  is permuted to cover all possible combinations, and the number of incidences is sorted according to the total internal energy of the molecule,

$$E = \sum_i n_i \nu_i. \quad (1.3)$$

As one can see from Fig. 1.5, for  $\text{SF}_6$ , the number of incidences where Eq. (1.2) is met, is orders of magnitude larger than for  $\text{CF}_2\text{Cl}_2$ . Also, the larger the excitation energy is, the bigger the difference between the two molecules. Note that for both molecules  $N$  increases rapidly with energy.

Figure 1.5 strongly suggests that  $\text{SF}_6$  will behave ergodically at a much lower excitation energy than  $\text{CF}_2\text{Cl}_2$ . Indeed, the experimental results presented in chapter 4 and 5 show that the intramolecular vibrational energy distribution of  $\text{SF}_6$  after infrared multiphoton excitation is an equilibrium one, while the one of  $\text{CF}_2\text{Cl}_2$  is not.

## 1.6 Mode-selective excitation vs. intramolecular vibrational energy equilibrium

The experimentally observed intramolecular equilibrium for dissociating molecules raised serious doubts regarding the feasibility of selective chemical bond breaking by infrared lasers. Experimental studies indicate that intramolecular energy relaxation takes

Fig. 1.5. Number of times,  $N$ , where Eq. (1.1) is satisfied as a function of excitation energy for  $\text{SF}_6$  and  $\text{CF}_2\text{Cl}_2$ . For  $\text{SF}_6$   $N$  is one to two orders of magnitude larger than for  $\text{CF}_2\text{Cl}_2$ . This graph suggests that  $\text{SF}_6$  will behave ergodically at a much lower excitation energy than  $\text{CF}_2\text{Cl}_2$ .

place on a picosecond time scale.<sup>34,35</sup> With today's molecular laser technology it is still hard to beat this time scale. It has been proposed that it may be possible to use laser pulses with a complicated preprogrammed coherence structure to match the evolution of the molecular states in such a way that the collective motion of the atoms leads to a selective bond breaking state.<sup>36</sup> However, this approach will work only when the time scale of the

coherence structure of the pumping pulse is shorter than the transverse relaxation time of the vibrational states. Practically, there is not yet a way to control the coherence structure of an infrared laser pulse on such a short time scale.

### 1.7 Objective of this work

Although the quasicontinuum model explains the general features of infrared multiphoton excitation, one cannot obtain a clear picture of intramolecular vibrational energy relaxation without measuring the intramolecular vibrational energy distributions. Most of the experiments done before this thesis do not supply mode-specific information other than for the pumped mode. Spectroscopic measurements on modes which do not interact directly with the infrared pumping laser are necessary for understanding how the nonresonant background modes participate in the infrared multiphoton excitation. In the first stage of this research project, time-resolved spontaneous Raman spectroscopy was employed to measure the vibrational energy of each accessible Raman active mode after infrared multiphoton excitation for molecules with different sizes and symmetries (see chapter 2–5). The intramolecular vibrational energy distributions were obtained as functions of infrared fluence, frequency and time. In the second stage, a high resolution coherent anti-Stokes Raman experiment was set up to measure the state-to-state population within each vibrational mode. In both cases, the realization of low density, high time resolution Raman spectroscopy provides direct measurements of the state of the molecules.
